Abstract: IgA vasculitis (IgAV) or Henoch-Schönlein purpura (HSP) is the most common vasculitis in children, and nephritis (IgAVN or HSPN) is the most important and only chronic manifestation of the disease. Despite this, there are no diagnostic criteria and we rely on the European League Against Rheumatism/Paediatric Rheumatology International Trials Organization/Paediatric Rheumatology European Society-endorsed Ankara 2008 classification criteria in our daily practice. Basic investigations that should be done in every patient with IgAVN include blood pressure measurement, estimated glomerular filtration rate and urinalysis. Kidney biopsy is still the gold standard for the diagnosis of IgAVN since noninvasive confirmation of nephritis is still pending. According to the Single Hub and Access point for pediatric Rheumatology in Europe (SHARE) recommendations, the first-line treatment for with mild forms of IgAVN is oral glucocorticoids, for patients with moderate IgAVN parenterally administered glucocorticoids in pulsed doses, while initial treatment for patients with the most severe forms of IgAVN include pulsed doses of glucocorticoids in combination with intravenous cyclophosphamide pulses. New therapeutic options are currently being tested, aiming to reduce the production of galactose-deficient IgA₁ and autoantibodies or suppress the alternative or lectin complement pathway and blocking mesangial cell activation.

Keywords: IgA vasculitis nephritis, clinical manifestations, proteinuria, hematuria, treatment

Introduction

IgA vasculitis (IgAV), formerly known as Henoch-Schönlein purpura, represents the non-granulomatous systemic vasculitis, histologically characterised by infiltration of the walls of the blood vessels, mainly arterioles, capillaries and venules, by neutrophils with deposits of immune complexes containing predominantly IgA in the endothelium of small blood vessels in the skin, synovial membrane, intestines and urinary system.^{1,2} IgAV is the most common systemic vasculitis in childhood, clinically manifested as purpuric rash accompanied by either gastrointestinal symptoms, arthritis, and/or nephritis.^{2,3} The main attribute of the disease is palpable purpura, which affects the lower extremities and buttocks.¹ By the 2012 revised Chapel Hill International Consensus Conference for Nomenclature of Vasculitides, the term HSP was replaced with IgAV.⁴

Despite the fact that the disease is most often self-limiting and lasts an average of up to four weeks, various acute and chronic complications are possible.^{5,6} Among the acute complications of the disease, the most frequent are those related to the gastrointestinal system, including intussusception, bowel perforation, and massive bleeding as the most serious ones.^{2,7} Nevertheless, the renal aspect of the disease is the most important chronic complication and the main cause of morbidity and mortality among children suffering from IgAV, and thus the main prognostic factor.^{2,8} Of note, it is necessary to distinguish IgA vasculitis nephritis (IgAVN) from IgA nephropathy (IgAN). Although these two diseases share many clinical, immunological and histological findings, there are also clinicopathological differences, not limited only the mere presence of extrarenal clinical signs in IgAV.^{9,10} This review article discusses the epidemiology, etiopathogenesis, clinical manifestations, with special emphasis on diagnosis and treatment of IgA vasculitis nephritis (IgAVN).

Epidemiology

The incidence of IgAV varies worldwide ranging from 3 to 27 cases per 100,000 children, while the prevalence varies between 6.1 and 20.4 per 100,000 children.^{1,11–13} IgAVN occurs in 20–60% of children suffering from IgAV.^{14,15} The highest occurrence of IgAV and IgAVN is found in East Asians, intermediate in Europeans, and the lowest in individuals of African ancestry.^{1,11} Furthermore, recently, it was demonstrated that both IgAV and IgAVN may not be randomly distributed in an area, but clustered more around cities.^{2,11} IgAVN showed linear clustering in the eastern part of Croatia, which follows the course of the Drava and Danube rivers, in the vicinity of areas of Balkan endemic nephropathy. The reasons for these geospatial variations of IgAV and IgAVN are not known, but it can be hypothesised that hotspot clusters appear where genetic and environmental factors substantially overlap.² This is another important difference between IgAVN and IgA nephropathy, which is predominantly associated with different genetic variants of innate immunity genes and genes important for defense against parasitic infections.¹⁶ The median age of onset is around 6 years, and 90% of patients are younger than 10 years, with males being more frequently affected than females at a ratio of 1.5:1.³

Etiopathogenesis

The etiopathogenesis of IgAV and IgAVN is reflected in the interaction of genetic and environmental factors, with special emphasis on infections.^{12,17} Studies investigating the genetic background of the disease were expected to identify candidate genes associated with IgAV susceptibility, particularly IgAVN.^{2,18} However, genome-wide association studies (GWAS) have indicated so far the significance of the HLA class II genes.^{19,20} It is important to emphasise that there are currently no large GWAS for pediatric IgAV and IgAVN, and only two small studies have been published to date. The results summarise the complex pathogenesis of IgAV caused primarily by interactions among a number of different genes, with a limited role played by each individual gene in disease development.² The first GWAS on IgAV susceptibility detected that the polymorphisms with the highest risk of developing disease were in the *HLA-DQA1* and *DQB1* intergenic zone and at the *HLA-DRB1*11* and *BI*13* loci.¹⁹ The second GWAS study found that haplotype *DQA1*01:01/DQB1*05:01/DRB1*01:01* was associated with susceptibility to IgAV but not with other autoimmune diseases.²⁰ The results of the GWAS to date classify IgAV as a prototype of a disease related to HLA class II loci, therefore sharing some features with giant cell arteritis and anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV).²

Although the exact etiology of the disease is not known, various infectious agents, drugs, vaccines, food allergens and insect bites may be precipitants triggering the onset of this disease in genetically predisposed individuals.^{7,17,21} In more than 75% of patients, upper respiratory tract or gastrointestinal infections precede the onset of disease. Multiple bacterial and viral infections have been described as triggers of IgAV: group A streptococcal infection (most common), infectious mononucleosis, subacute bacterial endocarditis, hepatitis, *Mycoplasma pneumoniae* infection, *Campylobacter* enteritis, *Helicobacter pylori* infection, *Yersinia* infection, *Shigella* infection, *Salmonella* infection, *Brucellosis*, *Legionella* species, Parvovirus, Adenovirus, Varicella-zoster virus infection, Rotavirus, etc.^{2,22,23} The role of infections in etiology and pathogenesis is further confirmed by observations of seasonal tendencies with fewer cases seen during the summer months and showing a peak in autumn and winter. Different non-infective triggers such as drugs (eg, ampicillin, erythromycin, penicillin, quinidine, quinine, losartan and cytarabine), vaccines, foods, cold temperatures and insect bites have been described to potentially be associated with a higher risk of developing IgAV.^{2,24}

According to some authors, two multi-hit pathogenesis models for IgAV and IgAVN are described.^{25,26}

In patients with IgAV, and especially in those patients who developed renal involvement, it seems that the aberrantly glycosylated IgA₁ plays a key role in the pathogenesis.² Specifically, IgA₁ from most patients with IgAV lack galactose residues (Gd-IgA₁). Aberrant glycosylation occurs predominantly due to decreased galactosyltransferase activity in the Golgi apparatus of IgA₁-producing immune cells. Gd-IgA₁ might be recognised as an autoantigen by IgA and IgG antibodies, leading to the formation of polymeric immune complexes (Gd-IgA₁-IgA, Gd-IgA₁-IgG and Gd-IgA₁-sCD89, where sCD89 is a soluble IgA Fc alpha receptor).² Circulating immune complexes may accumulate in the blood serum, resulting in their deposition in the endothelium of small blood vessels in the skin, synovial membrane, intestines and urinary system. It has been demonstrated that the serum level of Gd-IgA₁ is higher in IgAVN patients compared to IgAV

patients without nephritis.²⁷ In IgAV patients who developed IgAVN, some of these complexes, Gd-IgA₁-IgG, deposit in the kidneys, resulting in mesangial cell activation, release of inflammatory mediators and glomerular injury.²¹

Nonetheless, there is a second multi-hit hypothesis to explain the systemic symptoms of IgAV and IgAVN.²⁶ In this model, it is proposed that infection with microorganisms that have similar antigenic structures, as human vessel walls or genetic influences, could lead to the production of cross-reactive anti-endothelial cell antibodies (IgA₁-AECA). IgA₁-AECA bind to small vessels and induce the production of interleukin-8, which is a potent chemoattractant for neutrophils. Neutrophils become activated and cause damage to the vascular endothelial cells.²

However, none of the proposed models can explain the IgAV pathogenesis in the proportion of IgAV patients (<10%) who do not have elevated Gd-IgA₁ in serum or in biopsy specimens, nor can they explain the observation that the disease occurs only in some people with a IgA₁ glycosylation defect, while in others with elevated Gd-IgA₁ the disease does not occur.^{2,15,28}

IgAVN and Other Clinical Manifestations

Renal involvement ranges from urinary abnormalities (including hematuria or/and proteinuria) through nephritic and nephrotic syndrome to chronic renal failure.² It is typically mild and manifested only by pathological urine findings. However, chronic renal failure has been reported in 1 to 15% of children with IgAV who develop nephritis, and in the vast majority it is diagnosed within 6 months of disease onset.^{13,29,30}

Cutaneous manifestations in the form of nonthrombocytopenic purpura or petechiae with lower limb predominance are the most common and are a characteristic sign of the disease.¹ Alterations to the skin have proved to be a symptom in approximately 75% of patients, usually preceding other symptoms.³¹ They are present in all patients, but atypical distributions of skin changes are also possible, affecting the head and neck area, involving the upper extremities more than the lower extremities, sparing the lower extremities totally or otherwise leaving diffusely distributed lesions.² In the most severe cases, bullae, ulcerations and necrotic lesions can be seen. Such skin alterations developed in 2–3% of patients with IgAV and recently it was shown that with increasing severity and duration of cutaneous manifestations in IgAV, the risk of developing IgAVN increases, making the prognosis worse with a greater likelihood to have required more aggressive treatment.³² Furthermore, it was found that the presence of ulcerations and necroses, persistent purpura (more than 1 month) and age were significant predictors of IgAVN, while persistent purpura, male gender and age were predictors of persistent IgAVN (hematuria and/or proteinuria more than 3 months).³²

Musculoskeletal manifestations are the second most common feature and up to 70–90% of patients will have arthralgia or arthritis.³¹ The affected joints have painful ranges of movement due to periarticular swelling, but the characteristic findings of warmth, erythema and effusion are often absent.

Gastrointestinal manifestations are present in more than 50% of children with IgAV, and about 10–20% of patients with gastrointestinal involvement may develop serious complications such as intussusception, bowel perforation and massive bleeding.⁷ The abdominal pain is the most frequent sign of gastrointestinal involvement, and it is characteristically colicky and localised to the periumbilical and epigastric regions. According to newer study the patients with IgAV started with gastrointestinal symptoms, older children with severe gastrointestinal symptoms (severe abdominal pain, intussusception, hematochezia and/or massive gastrointestinal bleeding) of IgAV were a particularly high-risk group for developing IgAVN.³³

In 10–20% of boys, orchitis may develop. Other rare manifestations include lung involvement, neurological manifestations and multiple organ involvement.³⁴

Diagnostic Considerations

There are currently no diagnostic criteria for IgAV nor biomarkers in routine clinical use for IgAV and IgAVN in order to stratify patients with respect to the risk of developing kidney disease progression and contribute to the earlier diagnosis of renal involvement. For this reason, in our daily clinical practice we rely on classification criteria defined by the European League Against Rheumatism (EULAR), Paediatric Rheumatology International Trials Organization (PRINTO) and Paediatric Rheumatology European Society (PRES).¹ The criteria provide sensitivity and specificity in the classification of IgAV (using other forms of vasculitis as controls) at 100% and 87%, respectively. The mandatory criterion is

palpable purpura in association with at least one of the following: diffuse abdominal pain, arthritis or arthralgia, renal involvement (hematuria and/or proteinuria), and IgA deposition in biopsy specimens (skin, intestinal tract and kidney). A skin biopsy is not obligatory, but it is required in the event of atypically distributed skin change and is recommended if the rash is severe, in order to exclude other forms of vasculitis (Figure 1). The finding of a leucocytoclastic vasculitis associated with IgA deposition in a skin biopsy can help to accurately diagnose IgAV, but absence of IgA staining on biopsy does not exclude the diagnosis of IgAV.^{35,36}

Recently, the European initiative SHARE (Single Hub and Access point for pediatric Rheumatology in Europe) developed European consensus-based recommendations for diagnosis and treatment of immunoglobulin A vasculitis.³⁵

In all patients with IgAV blood pressure should be measured and renal involvement should be investigated using estimated glomerular filtration rate (eGFR) and urinalysis that includes assessment of hematuria and proteinuria with urine protein: urine creatinine ratio or urine albumin: urine creatinine ratio in an early morning urine sample.³⁵ If there is hypertension, macroscopic haematuria or significant proteinuria, investigations to consider are complete blood count with platelet count and differential, urea, serum creatinine and electrolyte levels, urinary protein-creatinine ratio, albumin and coagulation studies.

Kidney biopsy is still the gold standard for the diagnosis of IgAVN.² According to the SHARE guidelines, renal biopsy should be performed in patients with severe proteinuria defined as urine protein: urine creatinine ratio >250 mg/mmol for at

Figure 1 Diagnostic approach to IgAV and IgAVN. Data from Ozen et al.³⁵ Adapted from Jelusic M, Sestan M, Giani T, Cimaz R. New insights and challenges associated with IgA vasculitis and IgA vasculitis with nephritis-is it time to change the paradigm of the most common systemic vasculitis in childhood? *Front Pediatr.* 2022;10:853724. Creative commons.³⁶

least 4 weeks and persistent moderate proteinuria defined as urine protein: urine creatinine ratio 100–250 mg/mmol for at least 3 months or >50 mg/mmol for 6 months.³⁵ Impaired eGFR (<80 mL/min/1.73 m²) is also absolute indication for kidney biopsy. Relative indications include nephritic and/or nephrotic syndrome and/or worsening of renal function (rapidly progressive glomerulonephritis).

Several histological classifications are used in the analysis of renal biopsy findings in IgAVN, but it remains unknown which one has the strongest association with the severity and outcome.^{2,29} According to the analysis of histological classifications used in different parts of the world for IgAVN,²⁹ the most commonly used is that of the International Study of Kidney Disease in Children (ISKDC),^{37,38} followed by the revised Oxford classification.³⁹ In some parts of the world, histologic classification of IgA nephropathy of Haas and the modified semi-quantitative classification developed by a Finnish group of authors are used.^{40,41} Although the treatment recommendations of SHARE are based on the ISKDC classification, this classification is not without limitations, the most important of which is focusing only on glomeruli and active inflammation, neglecting vascular and tubulointerstitial changes.^{10,42} Meanwhile, the revised Oxford classification is increasingly being used. However, the working group of Oxford classification does not recommend its use in IgAVN since patients with IgAVN were not included in the validation cohort, and recent study showed that the Oxford classification could not be fully validated in IgAVN.^{39,43} On the other side, Finnish group of authors published the results according to which their modified semi-quantitative classification, the most complicated one, showed promising results with the need to include a larger number of patients to properly validate the classification.⁴¹ Most recently, international study on histologic classifications in IgAVN, which compared four previously mentioned classifications, demonstrated that the modified semi-quantitative classification followed by the Oxford classification are the best classifications to be used in renal biopsy analysis in patients with IgAVN.⁴⁴

There are currently no biomarkers in routine clinical use for IgAV and IgAVN; noninvasive confirmation of nephritis is still pending. Many potential biomarkers are currently under investigation, but an increased serum level of Gd-IgA₁ is still the most consistent finding in patients with IgAV.⁴⁵ Regarding urinary biomarkers, which have an advantage over blood biomarkers, because they are easier to collect, without using invasive procedures, IgA and IgM performed best in the study conducted by Pillebout et al²⁷ Many promising biomarkers in predicting nephritis are on the horizon: kidney injury molecule-1 (KIM-1), monocyte chemoattractant protein-1 (MCP-1), N-acetyl-β-glucosaminidase (NAG), and angiotensinogen (AGT).⁴⁶ Further studies are needed.

New approaches in the detection of potential biomarkers include the application of proteomics and metabolomics. Proteomics investigates protein interaction networks and identifies their biological functions. Using liquid chromatography-tandem mass spectrometry, Fang et al detected two proteins in the urine of IgAVN patients, integrin beta-1 and tenascin, that participate in multiple pathways in disease.⁴⁷ However, since only the level of tenascin was different among IgAVN children and IgAV children, they concluded that tenascin might be a novel biomarker of early renal damage in IgAVN. Metabolomics is a newly emerged field involved in the identification and quantification of metabolites in biofluids, cells and tissues. Several studies have applied metabolomics to reveal molecular mechanism of IgAVN pathogenesis and define potential biomarkers.^{48–50} Sun et al identified (S)-3-hydroxyisobutyric acid, p-Cresol sulfate, and 3-carboxy-4-methyl-5-pentyl-2-furanpropanoic acid that with high sensitivity and specificity may predict development of IgAVN among IgAV patients.⁴⁸ Demir et al suggest that DHAP (18:0), prostaglandin D2/I2, porphobilinogen, 5-methyltetrahydrofolic acid, and N-Acetyl-4-O-acetylneuraminic acid/N-Acetyl-7-O-acetylneuraminic acid may serve as biomarkers for predicting renal involvement in IgAV considering these metabolites were increased in IgAVN patients before the onset of renal involvement.⁴⁹ Zhang et al found that choline and *cis*-vaccenic acid could serve as biomarkers to predict the progression of IgAVN.⁵⁰ Further biological validation is expected.

In addition to urine analysis, renal and skin biopsy, other investigations may be required to rule out differentials if the diagnosis is unclear: blood and urine cultures, abdominal imaging, antistreptolysin O titer and anti-DNAse B while antinuclear antibodies (ANA), anti-double stranded DNA antibodies (dsDNA), ANCA, C3 and C4 may be necessary if there is significant renal involvement with an unclear diagnosis.⁵¹ In patients with IgAV leukocytosis with eosinophilia and a left shift may be observed and thrombocytosis is present in many of the patients. Erythrocyte sedimentation rate may be mildly elevated in the most patients. Elevation of blood urea nitrogen and creatinine indicate decreased kidney function. Stool guaiac test may reveal occult blood. It is possible to find coagulation disorders: D-dimer may be

substantially increased, while prothrombin time and activated partial thromboplastin time may be reduced. Serum IgA may be increased during the acute phase of illness but not in all patients.⁵¹

There are limited data for vasculitis activity and damage assessment in children with IgAV.² Since disease activity and damage have been recognised as the key components of outcome measures in patients with various forms of vasculitis for a standardised comparison of patient cohorts for clinical trials, as well for observing the course of an individual patient's disease, it is important to validate the available assessment tools adjusted for the pediatric population.^{2,52} Therefore, for the purpose of determining the disease activity and degree of kidney damage in patients with IgAV/IgAVN, two clinical questionnaires are used: the Paediatric Vasculitis Activity Score (PVAS) and Paediatric Vasculitis Damage Index (PVDI).

PVAS is a set of 64 clinical variables (symptoms or signs of disease) which are divided into 9 organ systems and it is assessed on which of them are new or have deteriorated in the previous 4 weeks or have persisted, but for no longer than a period of 3 months. The presence of each of the variables is evaluated with a certain number of points which are then added together. The total number of points is in the range from 0 to 63 points and represents the activity of the disease at the time of scoring.⁵²

PVDI represents a set of 72 clinical variables which are divided into 9 organ systems and an "other" section. Damage is defined by the duration of symptoms or signs lasting a period of at least 3 months, which have occurred at any time since the onset of the disease.⁵³

All patients with IgAV should be followed-up for at least 6–12 months even if the initial blood pressure measurements and urinalysis are normal.³⁵ The minimum set of tests includes blood pressure measurement and urinalysis for the presence of haematuria and quantification of albuminuria and/or proteinuria. It has not yet been defined whether the follow-up time should be extended for some groups of patients, ie, older children with the onset of gastrointestinal symptoms before other IgAV symptoms and severe GI form of IgAV, as well as those who develop ulcerations and necroses and persistent purpura, since they may be at higher risk for the later development of nephritis.^{32,33}

There are different suggestions for monitoring patients. According to one strategy, the initial urinalysis should be repeated three times.⁵⁴ In the case of normal findings, during the first month of follow-up, the urinalysis must be repeated once a week, then once a month during the next 6 months, and then once every 6 months. According to the second strategy, blood pressure measuring and urinalysis should be repeated weekly during the first month of the disease, then every 2 weeks in the second and third month, every month from the third to sixth month and then at 9th and 12th month.⁵⁵ Special attention should be paid to pregnant women with IgAVN with onset in childhood, because in these patients disease may complicate by hypertension and/or proteinuria.⁵⁶

Treatment Strategies

In the vast majority of patients with IgAV, during the self-limited nature of the disease, specific treatment is not required.² The optimal way to treat patients with severe skin manifestation is not known, although the majority of these patients are treated with systemic glucocorticoids, sometimes in combination with dapsone or azathioprine.³² Musculoskeletal involvement is usually treated with rest and analgesia, while other treatment options are rarely indicated. However, the total opposite can be recommended in patients with severe gastrointestinal manifestations, renal involvement or those who develop other complications such as lung involvement, neurological manifestations and multiple organ involvement.² There are two recommendations that can be used in the treatment with IgAVN (Table 1). The Kidney Disease: Improving Global Outcomes (KDIGO) practice guideline on glomerulonephritis is older and in one chapter provide recommendations for the treatment of IgAVN in children and adults.⁵⁷ European consensus-based recommendations for diagnosis and treatment of immunoglobulin A vasculitis developed by the SHARE initiative are newer ones.³⁵ The latter also provide information about the treatment of severe gastrointestinal manifestations. In patients with severe abdominal pain or gastrointestinal hemorrhage, glucocorticoids should be considered: orally, or with pulsed glucocorticoids if the oral route is not an option or if they fail to respond. Second-line treatments may include mycophenolate mofetil, cyclophosphamide, intravenous immunoglobulin, rituximab, methotrexate, colchicine and hydroxychloroquine.³¹ Other supportive treatment may be required: nasogastric decompression, parenteral nutrition and antibiotics.²

Table 1 Comparison of the SHARE and KDIGO Recommendations for Treatment of IgAVN

Parameter	SHARE Recommendations	KDIGO Recommendations
Isolated Hematuria	Follow-Up	No Recommendations
0.5–1 g/day proteinuria with normal eGFR	Oral prednisone angiotensin converting enzyme inhibitors or angiotensin receptor blockers if persists more than 3 months	Angiotensin converting enzyme inhibitors or angiotensin receptor blockers
1–2.5 g/day proteinuria with normal eGFR	Oral prednisone angiotensin converting enzyme inhibitors or angiotensin receptor blockers if persists more than 3 months	Angiotensin converting enzyme inhibitors or angiotensin receptor blockers and then glucocorticoids
>2.5 g/day proteinuria with no crescents or <50% of crescents	Oral prednisone and/or glucocorticoid pulses angiotensin converting enzyme inhibitors or angiotensin receptor blockers if persists more than 3 months	Angiotensin converting enzyme inhibitors or angiotensin receptor blockers and then glucocorticoids if no crescents glucocorticoids and cyclophosphamide if crescents
>2.5 g/day proteinuria with >50% of crescents	Cyclophosphamide pulses, glucocorticoid pulses then oral glucocorticoids angiotensin converting enzyme inhibitors or angiotensin receptor blockers if persists more than 3 months	Glucocorticoids and cyclophosphamide
eGFR <80 mL/min/1.73 m ² or deteriorating kidney function	Oral prednisone and/or glucocorticoid pulses if <50% of crescents cyclophosphamide pulses, glucocorticoid pulses then oral glucocorticoids if >50% of crescents	Glucocorticoids and cyclophosphamide

According to the SHARE management algorithm (Figure 2), IgAVN is divided into three categories, using three parameters: proteinuria, estimated glomerular filtration rate and percentage of crescents on a renal biopsy.³⁵ Children without renal dysfunction or proteinuria usually do not require any specific therapeutic intervention. First-line therapy in patients with mild forms of IgAVN, defined as ≤ 2.5 g/day of proteinuria in 24 h urine collection with normal estimated glomerular filtration rate, is oral glucocorticoids which are usually sufficient, and in the event of persistence of proteinuria, second-line drugs may be used: azathioprine, mycophenolate mofetil or glucocorticoid pulses. In the treatment of moderate IgAVN, defined as <50% crescents on a renal biopsy and an impaired estimated glomerular filtration rate (<80 mL/min/1.73 m²) or severe persistent proteinuria (>2.5 g/day of proteinuria in 24 h urine collection for more than 4 weeks), the preferred option is to use glucocorticoids, which usually need to be administered parenterally and in pulsed doses, and in the absence of any effect, second-line drugs are added: azathioprine, mycophenolate mofetil or cyclophosphamide parenterally. Treatment of the most severe forms of IgAVN consists of induction using pulsed doses of glucocorticoids in combination with intravenous

Figure 2 The SHARE recommendations for IgAVN treatment. Data from Ozen et al.³⁵ Jelusic M, Sestan M, Giani T, Cimaz R. New insights and challenges associated with IgA vasculitis and IgA vasculitis with nephritis-is it time to change the paradigm of the most common systemic vasculitis in childhood? *Front Pediatr.* 2022;10:853724. Creative Commons.³⁶

cyclophosphamide pulses, and continues as a maintenance therapy with lower doses of glucocorticoids in combination with immunomodulators: azathioprine or mycophenolate mofetil.^{2,35} Angiotensin converting enzyme inhibitors or angiotensin receptor blockers are recommended to prevent or limit secondary glomerular damage in patients with IgAVN who have persistent proteinuria (lasting a period of more than 3 months).

For the most severe, unresponsive cases, there is an option of plasma exchange which demonstrated an efficacy in one study, while there is not enough evidence regarding the use of rituximab (although it is used in severe cases, and there are case reports and case series concerning its usage) or intravenous immunoglobulins.^{31,58}

According to the KDIGO recommendations, patients with IgAVN are also divided into three categories, but they are defined differently.^{2,57} The mildest category is represented by patients with proteinuria 0.5–1 g/day per 1.73 m², for which treatment with angiotensin converting enzyme inhibitors or angiotensin receptor blockers is suggested. The second group consists of patients with proteinuria >1 g/day per 1.73 m². These patients should receive a 6-month course of glucocorticoid therapy after a trial of angiotensin converting enzyme inhibitors or angiotensin receptor blockers. Glucocorticoids and cyclophosphamide should be used in patients with crescentic IgAVN with nephrotic syndrome and/or deteriorating kidney function.

Knowledge of new pathogenetic mechanisms of IgAVN enables the development of new treatment strategies. They can be aimed at reducing production of Gd-IgA₁ and autoantibodies or on suppression of the alternative or lectin complement pathway and blocking mesangial cell activation.²¹ For now, these new therapeutic strategies are being tested mainly in IgA nephropathy, which some consider to be pathogenetically close to IgAV. Therapeutic options directed on the production of Gd-IgA₁ include oral budesonide, which can target Peyer's patches in the ileum, that are thought to be origin of Gd-IgA₁ production.⁵⁹ Another option targeting the similar mechanism is a proteasome inhibitor, bortezomib, which acts as a plasma cell depleting agent affecting the production of IgG autoantibodies.⁶⁰ Rituximab is a monoclonal antibody against surface cell marker on B cells, CD20, which may suppress the production of autoantibodies and reduce the synthesis of Gd-IgA₁. A systematic review from 2020 described clinical improvement and remission in significant percentage of patients with refractory IgAV.⁶¹ Complement inhibitors such as eculizumab and experimental drugs APL-2, CCX168, LNP023, and OMS721 represent new potential therapeutic targets and may be promising therapeutic interventions in the future.⁶² Recently, the spleen tyrosine kinase inhibitors demonstrated successful inhibition of pro-inflammatory responses in rat model of vasculitis with significant improvement of renal pathology and preserved renal function.⁶³

Conclusions

Although IgAV is the most common systemic vasculitis in children, and nephritis is its most important chronic complication, there are still open questions related to the diagnostic approach and treatment. The most important future steps will be to find non-invasive biomarkers that will correlate with the severity and prognosis of nephritis and to find new therapeutic options that will be based on the pathogenetic mechanisms of the disease.

Pediatric Health, Medicine and Therapeutics

Dovepress

Publish your work in this journal

Pediatric Health, Medicine and Therapeutics is an international, peer-reviewed, open access journal publishing original research, reports, editorials, reviews and commentaries. All aspects of health maintenance, preventative measures and disease treatment interventions are addressed within the journal. Practitioners from all disciplines are invited to submit their work as well as healthcare researchers and patient support groups. The manuscript management system is completely online and includes a very quick and fair peer-review system. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <http://www.dovepress.com/pediatric-health-medicine-and-therapeutics-journal>
